3 3. THE LARGE HADRON COLLIDER

4 3.1 *Introduction*

5 The Large Hadron Collider (LHC) is a 26.7 kilometer-long, two-ring particle
6 accelerator and collider located on the border of France and Switzerland at
7 the European Organization for Nuclear Research (CERN). During normal
8 operations the LHC maintains two counter-rotating beams of proton bunches
9 that collide at four interaction points (IP) with up to $\sqrt{s} = 14$ TeV center
10 of mass energy and a luminosity of $10^{34}\text{cm}^{-2}\text{s}^{-1}$. The ALICE (Point 2),
11 ATLAS (Point 1), CMS (Point 5), and LHC-b experiments each have a
12 detector at one of these interaction points as scene in Figure 3.1 . The CMS
13 and ATLAS are general-purpose detectors while LHC-b specializes in beauty
14 quark studies. ALICE is a heavy-ion experiment which uses $^{208}\text{Pb} - p$ or
15 $^{208}\text{Pb} - ^{208}\text{Pb}$ collisions that can also be produced by the LHC.

16 3.2 *Injection Complex*

17 In order to bring the protons from rest up to their target collision energy
18 a series of accelerators, as shown in Figure 3.2, are used. The acceleration
19 sequence begins with the injection of hydrogen gas into a duoplasmatron.
20 Here a bombardment of electrons ionize the hydrogen atoms while an electric
21 field pushes them through the duoplasmatron cavity. The result is 100 keV
22 protons being passed on to a quadrupole magnet which guides them into
23 the aperture of a linear accelerator (LINAC2). The radio frequency (RF)
24 cavities in LINAC2 accelerate the protons up to 50 MeV. At this point the
25 protons are sent into one of four rings in the Proton Synchrotron Booster
26 (PSB). The PSB repeatedly accelerates the protons around a circular path
27 until they reach an energy of 1.4 GeV. The bunches of protons from each PSB
28 ring are then sequentially injected into the single-ringed Proton Synchrotron
29 (PS). Each bunch injected into the PS are captured by one of the "buckets"
30 (Figure 3.3) provided by the PS RF system which also manipulates the
31 bunches into the desired profile and proton density. These proton bunches
32 are accelerated to 25 GeV and injected into the Super Proton Synchrotron

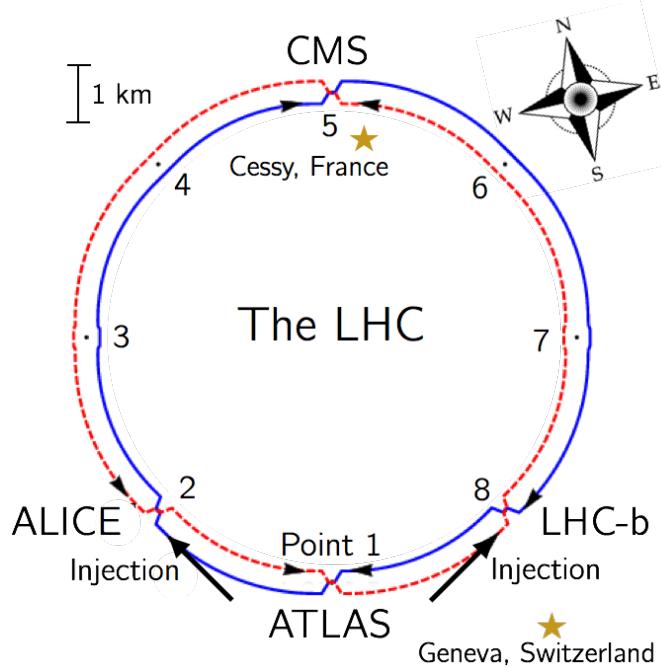

Fig. 3.1: Interaction points of the LHC

³³ (SPS) where they are accelerated to 450 GeV. Finally the proton bunches
³⁴ are injected into the LHC ring where they are accelerated to 6.5 TeV and
³⁵ collided in 25 ns intervals to yield a center of mass energy of $\sqrt{s} = 13$ TeV.

³⁶ 3.3 Tunnel and Magnets

³⁷ The LHC was designed to produce collisions with up to $\sqrt{s} = 14$ TeV. That
³⁸ requires confining and guiding 7 TeV protons around the circumference of
³⁹ the LHC ring. The ring is housed in a 4 meter-wide underground tunnel
⁴⁰ that ranges in depth between 45 and 170 meters below the surface. This
⁴¹ tunnel was repurposed from the Large Electron-Positron (LEP) Collider
⁴² which previously occupied the space. For this reason the tunnel is not
⁴³ completely circular but is instead made up of alternating curved and straight
⁴⁴ sections of 2500 m and 530 m in length respectively. The straight sections,
⁴⁵ labeled 1-8 in Figure 3.1, are used as either experimental facilities or sites for
⁴⁶ hardware necessary for LHC operations such as RF cavities for momentum
⁴⁷ cleaning, quadrupole magnets for beam focusing, and sextupole magnets for
⁴⁸ acceleration and betatron cleaning.

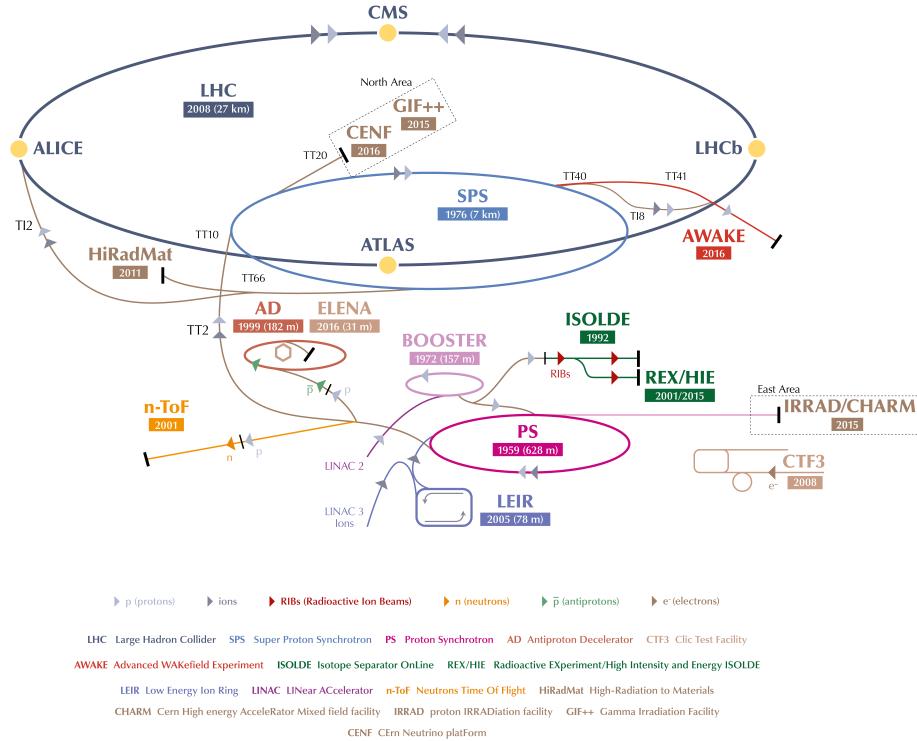

Fig. 3.2: Layout of LHC accelerator complex [16].

49 Steering a 7 TeV proton beam around the curved sections requires a mag-
 50 netic field of 8.33 Tesla which is provided by 1223 superconducting dipole
 51 magnets cooled to 1.9 K. A cross section of the LHC dipole is shown in
 52 Figure 3.4. Supercooled liquid helium flows through the heat exchanger
 53 pipe to cool the iron yolk to a temperature of 1.9 K. Ultra high vacuum
 54 is maintained in the outer volume to provide a layer of thermal insulation
 55 between the inner volume and the outer steel casing. Inside the iron yolk is a
 56 twin bore assembly of niobium-titanium superconducting coils. Two parallel
 57 beam pipes are located within the focus of the superconducting coils. This
 58 is the ultra high vacuum region where the subatomic particles are confined
 59 as they travel around the LHC ring.

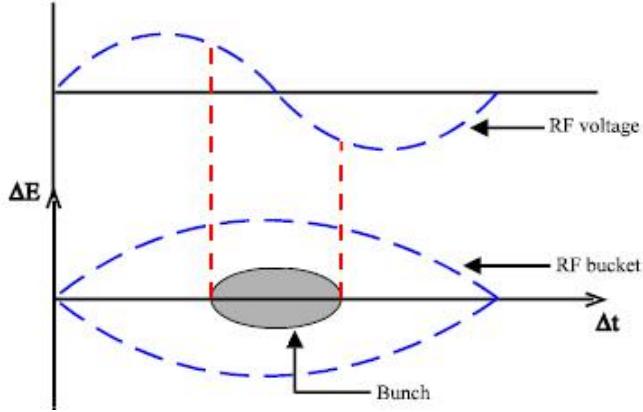

Fig. 3.3: Proton bunch capture onto RF bucket [6].

3.4 Luminosity

61 The number of events generated per second for specific process having cross-
62 section σ_{event} is given by:

$$\frac{dN_{event}}{dt} = L\sigma_{event} \quad (3.1)$$

63 where L is the machine luminosity. The machine luminosity for a Gaussian
64 beam distribution can be written in terms of the beam parameters as:

$$L = \frac{N_b^2 n_b f_{rev} \gamma_r}{4\pi \epsilon_n \beta_*} F \quad (3.2)$$

65 where N_b is particle density in each bunch, n_b is the number of bunches
66 in each beam, f_{rev} is the frequency of revolution, and γ_r is the relativistic
67 gamma factor. The variables ϵ_n and β_* are the normalized transverse beam
68 emittance and the beta function at the IP respectively, while F is the geo-
69 metric reduction factor depending due to the beams' crossing angle at the
70 IP. [16]

71 The total number of events produced over a given amount of time would
72 then be

$$N_{event} = \sigma_{event} \int L dt = \sigma_{event} L_{integrated}. \quad (3.3)$$

73 The integrated luminosity delivered each year to the CMS experiment is
74 shown in 3.5. The analysis presented here uses data collected from the 2016,
75 2017, and 2018 campaigns which gives a combined integrated luminosity of
76 158.7 fb^{-1} .

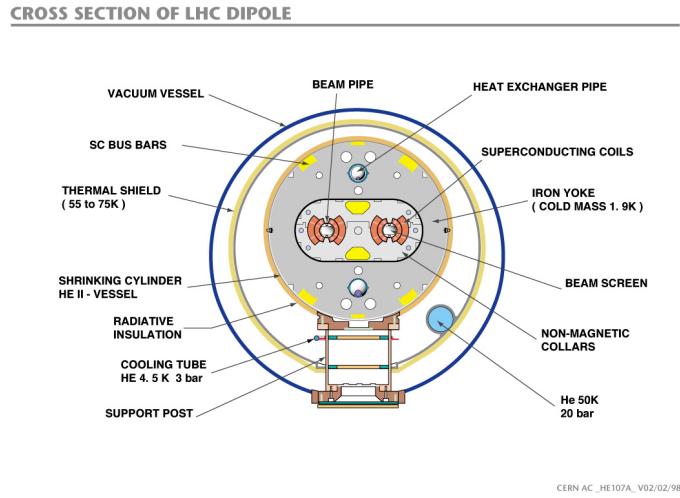

Fig. 3.4: Cross section of LHC dipole [9]

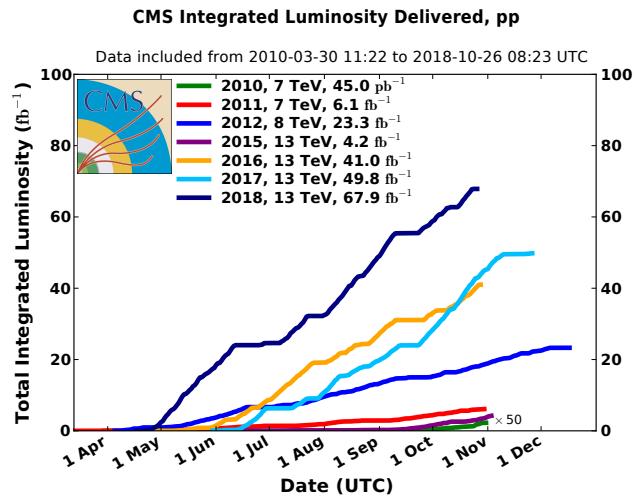

Fig. 3.5: Integrated luminosity delivered by the LHC to the CMS experiment each year from 2010-2018.

4. COMPACT MUON SOLENOID

4.1 Introduction

79 About 100 meters below the town of Cessy, France at Point 5 is the Compact
 80 Muon Solenoid (CMS). The CMS is a general purpose detector weighing
 81 14,000 tonnes with a length of 28.7 meters and a 15.0-meter diameter that
 82 was designed to accurately measure the energy and momentum of particles
 83 produced in the proton-proton or heavy-ion collisions at the LHC [13]. A
 84 perspective view of the detector is shown in Figure 4.1. In order to get
 85 a full picture of what is being produced by the collisions the CMS detector
 86 must be able identify the resulting particles as well as accurately measure
 87 their energy and momentum. For this reason the detector was designed to
 88 be a collection of specialized sub-detectors, each of which contributes data
 used in the reconstruction of a collision.

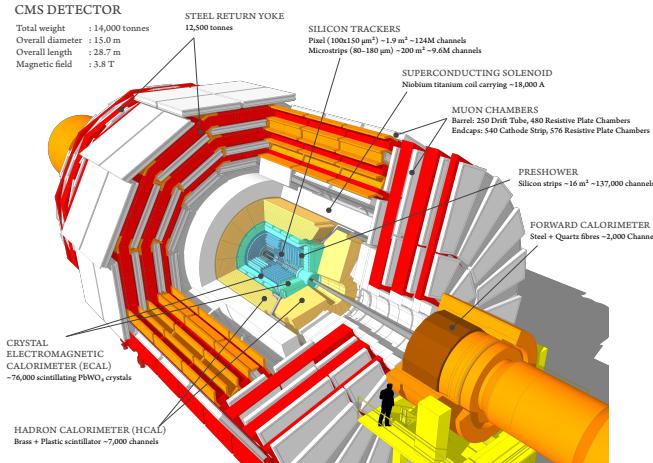

Fig. 4.1: Schematic of CMS detector [18]

90 At the heart of the CMS detector is a 3.8-Tesla magnetic field produced
 91 by a superconducting solenoid. Inside the 6-meter diameter solenoid are

three layers of sub-detectors. These make up the inner detector and are, in order from innermost to outermost, the silicon tracker, the electromagnetic calorimeter (ECAL), and the hadronic calorimeter (HCAL). Outside the solenoid is the muon system. A transverse slice of the detector (Figure 4.2) shows the sub-detectors and how different types of particles interact with them. Table 4.1 shows a summary of which sub-detectors are expected to produce signals for different types of particles.

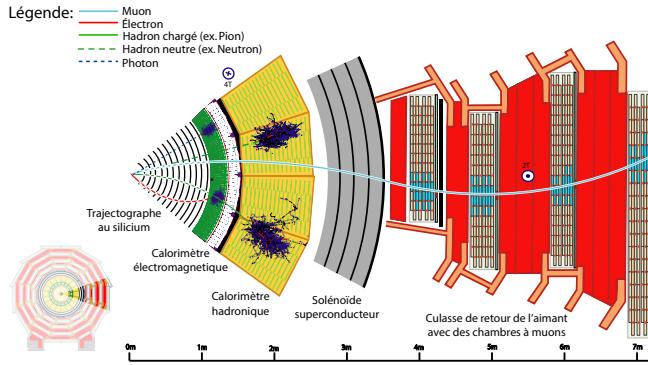

Fig. 4.2: Transverse slice of the CMS detector[7].

Particle	Tracker	ECAL	HCAL	Muon
Photons	No	Yes	No	No
Electrons	Yes	Yes	No	No
Hadrons (charged)	Yes	Yes	Yes	No
Hadrons (neutral)	No	No	Yes	No
Muons	Yes	Yes	Yes	Yes
Invisible (ν , SUSY, etc)	No	No	No	No

Tab. 4.1: Summary of signals expected for each particle type in each sub-detector.

4.2 Coordinate System

The origin of the coordinate system used by CMS is centered at the nominal collision point in the center of the detector. A right-handed Cartesian system is used with the x-axis pointing radially inward toward the center of the LHC ring, y-axis pointing vertically upward, and the z-axis pointing tangent to

104 the LHC ring in the counterclockwise direction as viewed from above. CMS
 105 also uses an approximately Lorentz invariant spherical coordinate system
 106 spanned by three basis vectors. They are the transverse momentum p_T ,
 107 pseudorapidity η , and azimuthal angle ϕ . The transverse momentum and
 108 azimuthal angle translate to the Cartesian system in the following ways
 109 using the x and y-components of the linear momentum:

$$p_T = \sqrt{(p_x)^2 + (p_y)^2} \quad (4.1)$$

$$\phi = \tan^{-1} \frac{p_y}{p_x} \quad (4.2)$$

110 while the pseudorapidity can be translated using the polar angle θ relative
 111 the positive z-axis as

$$\eta = -\ln[\tan \frac{\theta}{2}] \quad (4.3)$$

113 4.3 Tracker

114 The innermost sub-detector in CMS is the silicon tracker. The tracker is
 115 used to reconstruct tracks and vertices of charged particles. In order to give
 116 precise reconstruction of charged particle trajectories it needs to be position
 117 as close as possible to the IP and have high granularity. The close proximity
 118 to the IP requires the materials to be tolerant to the high levels of radiation
 119 in that region. Being the innermost sub-detector it must also minimally
 120 disturb particles as they pass through it into the other sub-detectors. These
 121 criteria led to the design of the tracker using silicon semiconductors.

122 The silicon tracker is made up of two subsystems, an inner pixel detector
 123 and an outer strip tracker which are oriented in a cylindrical shape with an
 124 overall diameter of 2.4 m and length of 5.6 m centered on the interaction
 125 point. Both subsystems consist of barrel and endcap regions which can be
 126 seen in Figure 4.3.

127 4.3.1 Pixel Detector

128 The pixel detector is the innermost subsystem in the silicon tracker and
 129 spans the pseudorapidity range $|\eta| < 2.5$ and is responsible for small im-
 130 pact parameter resolution which is important for accurate reconstruction of
 131 secondary vertices [13]. In order to produce these precise measurements a
 132 very high granularity is required. In addition to this the proximity to the
 133 IP means that one expects there to be high occupancy of the tracker. These
 134 constraints are met by using pixels with a cell size of $100 \times 150 \mu\text{m}^2$.

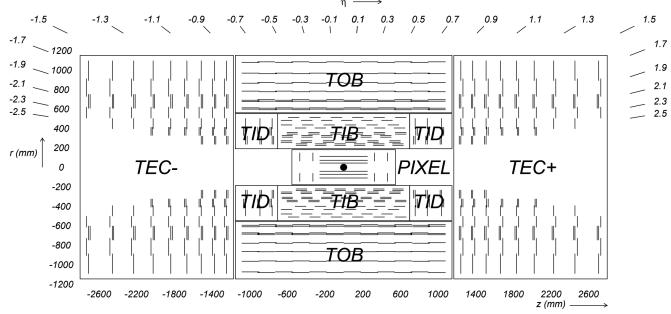

Fig. 4.3: Cross section (side) of CMS tracker prior to the Phase 1 upgrade during the year-end technical stop of 2016/2017. Each line represents a detector module while double lines indicate back-to-back strip modules. Surrounding the pixel tracker (PIXEL) is the strip detector, which is divided into the Tracker Inner Barrel (TIB), Tracker Outer Barrel (TOB), Tracker Inner Disks (TID), and Tracker Endcaps (TEC). Reprinted from Reference [12].

135 The original pixel detector was designed for operation at the nominal
 136 instantaneous luminosity of $10^{34} \text{ cm}^{-2}\text{s}^{-1}$ with 25 ns between proton bunch
 137 crossings, resulting in on average about 25 proton-proton interactions occur-
 138 ring per bunch crossing or pileup [12]. During the LHC technical shutdown
 139 of 2016/17, the pixel detector underwent the scheduled Phase 1 upgrade
 140 which would allow operation at higher levels of instantaneous luminosity
 141 and pileup. Figure 4.4 shows a cross sectional view in the r - z plane. Prior
 142 to 2017 there were three barrel layers and two endcap layers on each side
 143 which provide three very precise space points for each charged particle. The
 144 upgrade decreased the radius of the innermost barrel layer from 4.4 cm to
 145 3.0 cm and added a fourth barrel layer as well as adding third endcap layer
 146 to each side. Each of the endcap layers consisted of two half-disks populated
 147 with pixel modules whereas the upgraded endcap layers were split into inner
 148 and outer rings. [11]

149 4.3.2 Strip Detector

150 The silicon strip detector surrounds the pixel detector and is comprised of
 151 four subsystems, the Tracker Inner Barrel (TIB), the Tracker Outer Barrel
 152 (TOB), the Tracker Inner Disks (TID), and the Tracker Endcaps (TEC),
 153 all of which can be seen in Figure 4.3 [13]. The TIB and TID both use
 154 320 μm thick silicon micro-strip sensors oriented along z and r respectively.
 155 The TIB has four layers while the TID is composed of three layers. This

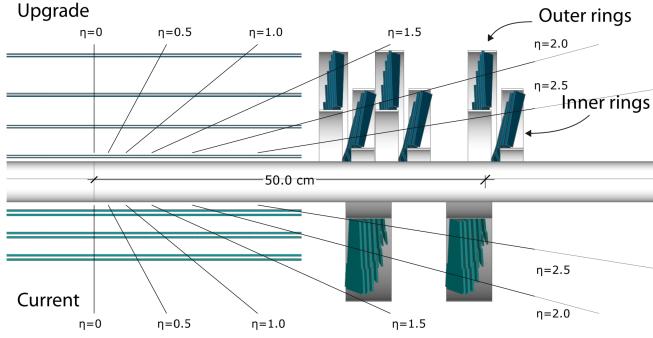

Fig. 4.4: Cross section (side) of pixel detector. The lower half , labeled "Current", shows the design prior to 2017 while the upper half, labeled "Upgrade", shows the design after the upgrade. Reprinted from Resource [11]

geometry allows the TIB and TID to combine to provide up to four $r - \phi$ measurements on charged particle trajectories.

Surrounding the TIB and TID is the TOB, which extends between $z \pm 118$ cm. This subsystem consists of six layers of 500 μm thick silicon micro-strip sensors with strip pitches ranging from 122 μm to 183 μm , providing six more $r - \phi$ measurements in addition to those from the TIB/TID subsystems. Beyond the z range of the TOB is the TEC. Each TEC is made up of nine disks. Each of the nine disks has up to seven concentric rings of micro-strip sensors oriented in radial strips with those on the inner four rings being 320 μm thick and the rest being 500 μm thick, providing up to nine ϕ measurements for the trajectory of a charged particle.

To provide additional measurements of the z coordinate in the barrel and r coordinate in the disks a second micro-strip detector module is mounted back-to-back with stereo angle 100 mrad in the first two layers of the TIB and TOB, the first two rings of the TID, and rings 1, 2, and 5 of the TEC. The resulting single point resolution is 230 μm in the TIB and 530 μm in the TOB. The layout of these subsystems ensures at least nine hits for $|\eta| < 2.4$ with at least four of hits yielding a 2D measurement.

4.4 Electromagnetic Calorimeter

The electromagnetic calorimeter (ECAL) lies just outside the tracker and is a hermetic homogeneous calorimeter designed to measure the energy deposited by electrons and photons. It consists of a central barrel (EB) with 61200 lead tungstate (PbWO_4) crystals which is closed by two endcaps (EE), each

179 having 7324 crystals. Highly-relativistic charged particles passing through a
180 crystal primarily lose energy by producing bremsstrahlung photons. Photons
181 lose energy by producing $e^- - e^+$ pairs. In front of each EE is a preshower
182 (ES) detector which acts as a two-layered sampling calorimeter. The crystals
183 in the EB are instrumented with avalanche photodiodes (APDs) while the
184 EE crystals are instrumented with vacuum phototriodes (VPTs). The ECAL
185 design was strongly driven to be sensitive to the di-photon decay channel
186 of the Higgs boson. This led to the design of a calorimeter that was fast,
187 radiation-hard, and had good spatial and energy resolution.

188 4.4.1 Crystals

189 In order to provide a good spacial resolution it was necessary for the ECAL
190 to have a fine granularity. The small Molier radius (22 mm) and short radia-
191 tion length (8.9 mm) of PbWO₄ allows for fine granularity while maintaining
192 good energy resolution by containing nearly all of the energy from an EM
193 shower without the need for a restrictively thick crystal layer. The PbWO₄
194 scintillation is also fast enough that approximately 80 percent of an EM
195 shower is produced within 25 ns, which is the also the amount of time be-
196 tween bunch crossings at the LHC. These crystals have a Gaussian-shaped
197 spectrum spanning from 360 nm to 570 nm with a maximum at approx-
198 imately 440 nm. While PbWO₄ is relatively radiation-hard, the amount
199 of ionizing radiation seen by the crystal leading up to the HL-LHC era of
200 operations causes wavelength-dependent degradation in light transmission.
201 The scintillation mechanism however is unchanged so this damage can be
202 tracked and accounted for by injecting laser light near the peak wavelength
203 of the emission spectrum into the crystals to monitor optical transparency.

204 Light produced in the crystal is transmitted along its length and col-
205 lected at the rear by either an APD in the EB or a VPT in one of the EE.
206 Light output is temperature dependent so the crystals are kept at precisely
207 18°C at which the yield is about 4.5 photoelectrons per MeV. The EB and
208 EB crystals, which have a tuncated pyramidal shape to match the lateral de-
209 velopment of the shower, along with their photosensors are shown in Figure
210 4.5.

211 4.4.2 Barrel and Endcaps

212 The EB covers the pseudorapidity range $|\eta| < 1.479$ and uses crystals that
213 are 230 mm long, which corresponds to 25.8 radiation lengths. The front
214 face of each crystal measures 22×22 mm² while the rear face measures 26×26

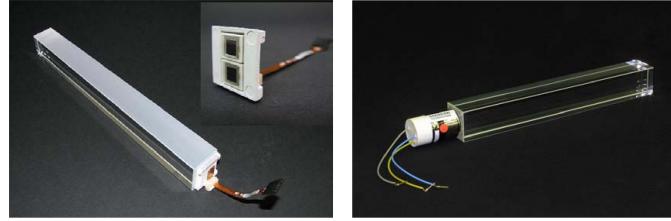

Fig. 4.5: PbWO₄ crystals. Left: EB crystal with APD. Right: EE crystal with VPT. Reprinted from [13]

mm². These are grouped in 36 supermodules (SM), each comprised of 1700 crystals arranged in a 20×85 grid in $\phi \times \eta$. Each SM spans half the length of the barrel and covers 20° in ϕ . On the back face of each crystal is a pair of APDs (semiconductor diodes). APDs are compact, immune to the longitudinal 3.8 T magnetic field produced by the solenoid at this location, and resistant to the radiation levels expected in the EB over a ten year period. They also have high enough gain to counter to low light yield of the crystals. All of this makes them an ideal choice for use in the EB. Each APD has an active area of 5 × 5 mm² and are operated at a gain of 50 which requires a bias voltage between 340 and 430 V. As the gain of the APDs is highly dependent on the applied bias voltage and any gain instability would translate to degradation in energy resolution, very stable power supplies are used to maintain voltages within a few tens of mV.

The EE cover the pseudorapidity range 1.497 < | η | < 3.0. The crystals in the EE have a 28.62×28.62 mm² front face cross section and 30×30 mm² rear face cross section. Each crystal is 220 mm long which corresponds to 24.7 radiation lengths and are grouped in 5×5 units called supercrystals (SCs). Two halves, called *Dees*, make up each EE. Each Dee contains 138 SCs and 18 partial SCs which lie along the inner and outer circumference. On the back of each crystal in EE is a VPT which is a conventional photomultiplier with a single gain stage. While not as compact as the APDs used in the EB, the VPTs are a more suitable for the more hostile environment at higher η . Each VPT has a 25-mm diameter and approximately 280 mm² of active area. Though the VPT gain and quantum efficiency are lower than that of the APDs this is offset by the larger active area allowing for better light collection. Figure 4.6 shows the orientation of the crystals, modules, and supermodules within the ECAL. [13]

242

4.4.3 Preshower layer

243 In front of each EE is a preshower (ES) detector. The main purpose of the
 244 ES is to identify photons resulting from $\pi^0 \rightarrow \gamma\gamma$ within the pseudorapidity
 245 range $1.653 < |\eta| < 2.6$, but it also aids in the identification of electrons
 246 against minimum ionizing particles (MIPs) and provides a spacial resolution
 247 of 2 mm compared to the 3 mm resolution of the EB and EE. The ES acts
 248 as a two-layered sampling calorimeter. Lead radiators make up the first
 249 layer. These initiate electromagnetic showers from incoming electrons or
 250 photons. The deposited energy and transverse profiles of these showers are
 251 then measured by the silicon strip sensors which make up the second layer.

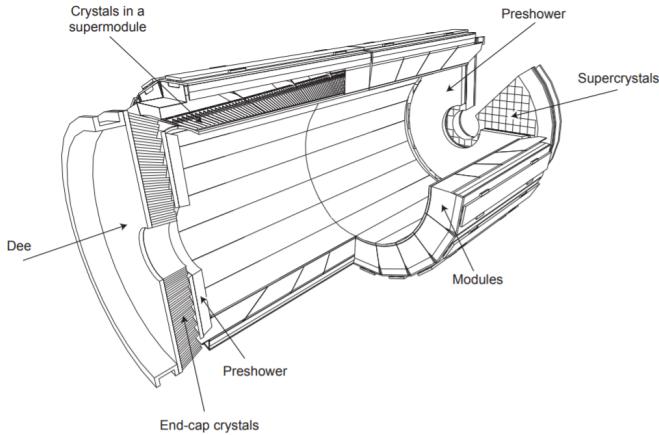

Fig. 4.6: Schematic of ECAL. Reprint from [13]

252

4.4.4 Performance

253 The energy resolution of the ECAL can be parameterized as

$$\frac{\sigma}{E} = \frac{S}{\sqrt{E}} \oplus \frac{N}{E} \oplus C \quad (4.4)$$

254 where S is the stochastic term characterizing the size of photostatistical
 255 fluctuations, N is the term characterizing the contributions of electronic,
 256 digital, and pileup noise, and C is a constant which accounts for crystal
 257 performance non-uniformity, intercalibration errors, and leakage of energy
 258 from the back of a crystal. The values for these terms, as measured in a
 259 beam test using 20 to 250 GeV electrons, are $S = 0.028 \text{ GeV}^{1/2}$, $N = 0.12$
 260 GeV, and $C = 0.003$. [13]

 261 4.5 Hadronic Calorimeter

262 In the space between the bore of the superconducting magnet and the ECAL
 263 is the Hadronic Calorimeter (HCAL) [2]. The HCAL is a sampling calorime-
 264 ter used for the measurement of hadronic jets and apparent missing trans-
 265 verse energy resulting from neutrinos or exotic particles. It is made up of al-
 266 ternating layers of plastic scintillator tiles and brass absorbers. EM showers
 267 are generated by charged/neutral hadrons in the brass absorber. Charged
 268 particles in the shower then produce scintillation light in the plastic scintil-
 269 lator. Wavelength-shifting optical fibers embedded in the scintillator collect
 270 and guide the scintillation light to pixelated hybrid photodiodes. A longi-
 271 tudinal cross-section view in Figure 4.7 shows the geometric layout of the
 272 HCAL’s barrel (HB), outer barrel (HO), endcap (HE), and forward (HF)
 273 sections. The HB is comprised of 17 scintillator layers extending from 1.77
 274 to 1.95 m and covers the pseudorapidity range of $|\eta| < 1.4$. The HO lies
 275 outside the solenoid and is composed of only scintillating material. This
 276 increases the interaction depth of the calorimeter system to a minimum of
 277 $11\lambda_I$ for $|\eta| < 1.26$ and thus reduces energy leakage. Also located inside
 278 the solenoid are the two HE which cover pseudorapidities $1.3 < |\eta| < 3.0$
 279 and provide a thickness of $10\lambda_I$. In the forward region is the HF. This is
 280 located 11.2 m away from the IP and covers the $2.9 < |\eta| < 5.2$. As the
 281 HF is exposed to the highest levels of particle flux, it uses quartz fibers em-
 282 bedded in steel absorbers rather than the materials used in the other parts
 283 of the HCAL. Showers initiated by the absorbers produce Cerenkov light
 284 in the quartz which transmits along to the fibers to photomultiplier tubes
 285 (PMTs).

286 The HCAL inherently has lower energy resolution than the ECAL. A
 287 large portion of the energy from hadronic showers is deposited in the ab-
 288 sorbers and never makes it to the scintillation material. There are also
 289 the possibilities that showers can be initiated prior to the particles reach-
 290 ing HCAL or a charged particle could deposit energy in the ECAL through
 291 bremsstrahlung. The combined energy resolution of the ECAL and the
 292 HCAL barrels can be parameterized as

$$\frac{\sigma}{E} = \frac{S}{\sqrt{E}} \oplus C, \quad (4.5)$$

293 where E is the energy of the incident particle. These quantities were mea-
 294 sured in a beam test using 2 to 350 GeV/c hadrons, electrons, and muons.
 295 The stochastic term is $S = 0.847 \text{ GeV}^{1/2}$, and the constant term is $C = 0.074$
 296 [4].

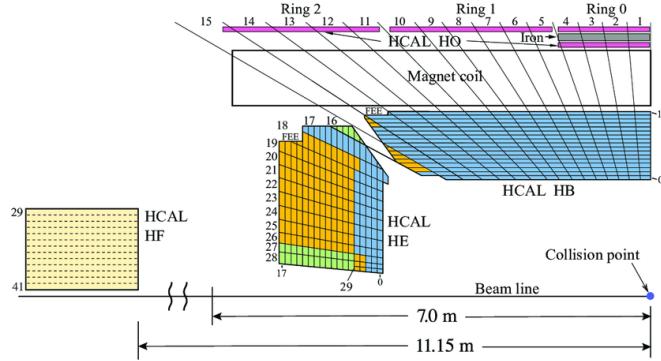

Fig. 4.7: Longitudinal view of HCAL [2]

297 4.6 Superconducting Solenoid

298 In between the HCAL barrel and outer barrel is the superconducting solenoid
 299 magnet. The magnet is 12 m long with a 6-m inner diameter and provides
 300 the bending power necessary to precisely measure the momentum of charged
 301 particles. While it is capable of producing a 4 T magnetic field, the magnet
 302 is typically operated at 3.8 T. This is done to prolong the lifetime of the
 303 magnet. The Niobium Titanium coils used to create the uniform 3.8-T
 304 magnetic field are suspended in a vacuum cryostat and cooled by liquid helium
 305 to a temperature of 4.5 K. The magnet has a stored energy of 2.6 GJ when
 306 operating at full current. There are five wheels in the barrel and three
 307 disks on each endcap that make up a 12,000 ton steel yoke which serves to
 308 return the magnetic flux. This, along with a mapping of the calculated field
 309 strength, can be seen in Figure 4.8. More details on the superconducting
 310 solenoid magnet can be found at [1]

311 4.7 Muon System

312 Embedded in magnet return yoke and encapsulating all of the other sub-
 313 detectors is the muon system. The muon system is the outermost layer
 314 because muons don't interact via the strong force and electromagnetic in-
 315 teractions alone are not enough to stop them due to their large mass, therefore
 316 the only particles that are capable of making it to the muon system are
 317 muons and weakly-interacting particles such as neutrinos. The muon sys-
 318 tem is comprised of three different types of detectors. These are drift tube
 319 (DT) chambers, cathode strip chambers (CSC), and resistive plate chambers

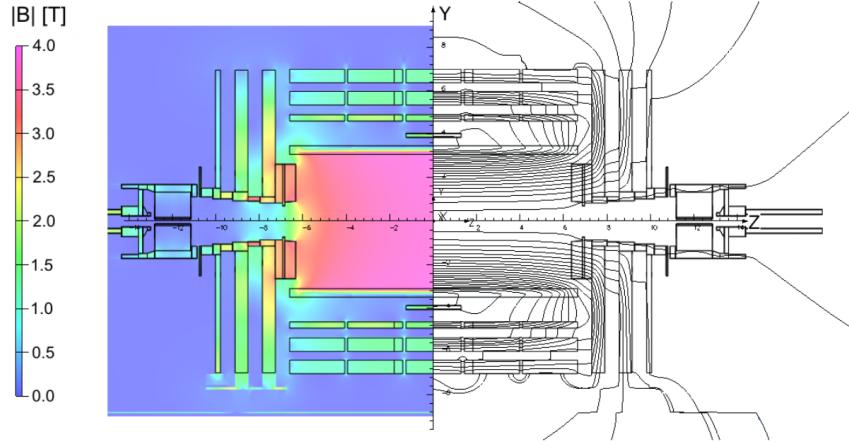

Fig. 4.8: Longitudinal slice of CMS detector while operating at 3.8-T central magnetic field. The right-hand side of the figure shows a mapping of the magnetic field lines while the left-hand side shows a mapping of the field strength. Reprint from [10]

320 (RPC). A cross-sectional view of the muon system along with the rest of the
 321 CMS detector is shown in Figure 4.9.

322 The DT chambers are used barrel region for $|\eta| < 1.2$. Each chamber is
 323 comprised of three superlayers which are made up of four staggered layers
 324 of rectangular drift cells. Each of these drift cells contains a mixture of
 325 Ar and CO₂ gases. An anode wire, located at the center of each tube, is
 326 made of gold-plated stainless steel and is held at 3.6 kV. The gas is ionized
 327 when a charged particle passes through and the resulting free electrons are
 328 attracted to the anode wire. As these electrons pass through the gas they
 329 cause further ionization which results in an electron avalanche. The layers
 330 of drift cells are oriented in such a way that two of the three superlayers
 331 give the muon position in the ϕ -direction and one gives the position in the
 332 z -direction. The result is a spacial resolution of 77-123 μm along the ϕ
 333 direction and 133-193 μm along the z direction for each DT chamber [14].

334 On the endcaps, covering the pseudorapidity range of $0.9 < |\eta| < 2.4$,
 335 are the CSCs. In this region there is a higher muon flux as well non-uniform
 336 magnetic fields so this portion of the muon system must have higher gran-
 337 ularity provided by the CSCs. Each of these chambers contain panels that
 338 divide it into six staggered layers. The cathode strips are oriented along the
 339 r -direction to give position measurements in the ϕ -direction while anode
 340 wires run perpendicular in between the panels to give r -direction position

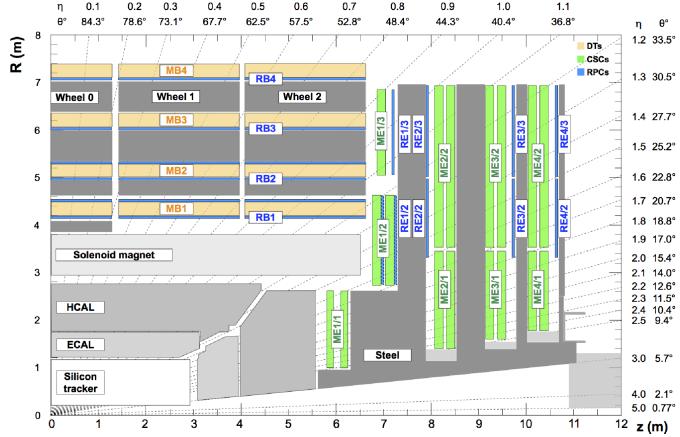

Fig. 4.9: Cross-section of one quadrant of the CMS detector. The DTs are labeled as "MB" (Muon Barrel) and the CSCs are labelled as "ME" (Muon Endcap). The RPCs are "RB" for those in the barrel and "RE" for those in the endcap. Reprint from [19].

341 measurements. The spacial resolution provided by the CSCs is 45-143 μ m
 342 [19].

343 Both the endcap and barrel regions, spanning $|\eta| < 1.6$, contain RPCs to
 344 provide more precise timing measurements. Each RPC is a gaseous parallel-
 345 plate detector. High voltage is applied to two large plates which have a
 346 layer of gas between them. Outside the chamber is an array of cathode
 347 strips which is used to detect electron cascades resulting from muons passing
 348 through and ionizing the gas. Where the DTs and CSCs provide precise
 349 position information, the RPCs have a very fast response time which gives
 350 a time resolution better than 3 ns [19]. This allows for the RPCs to be used
 351 as a dedicated muon trigger that can insure each muon is assigned to the
 352 correct bunch crossing.

353

5. MIP TIMING DETECTOR (MTD)

354

5.1 Introduction

355 In the coming years the LHC will be working toward upgrades that will
 356 lead a substantial increase in luminosity. The timeline for future operations
 357 of the LHC is shown in Figure 5.1. In 2019 the LHC entered a two-year
 358 shutdown, Long Shutdown 2 (LS2). Upgrades of the LHC injector complex
 359 to increase the beam brightness will take place during this shutdown. After
 360 LS2 the LHC will enter Run 3 which will run for three years at 13-14 TeV. At
 361 the completion of Run 3 the LHC will enter Long Shutdown 3 (LS3) which
 362 will last approximately 2.5 years. During LS3 the optics in the interaction
 363 region will be upgraded to produce smaller beams at the interaction point.
 364 The completion of this upgrade will usher in the High Luminosity (HL-LHC)
 365 era or Phase 2 of LHC operations, during which the combination of brighter
 366 beams and a new focusing scheme at the IP allows for a potential luminosity
 367 of $2 \times 10^{35} \text{ cm}^{-2}\text{s}^{-1}$ at the beginning of each fill [5].

LHC/ High-Luminosity LHC timeline

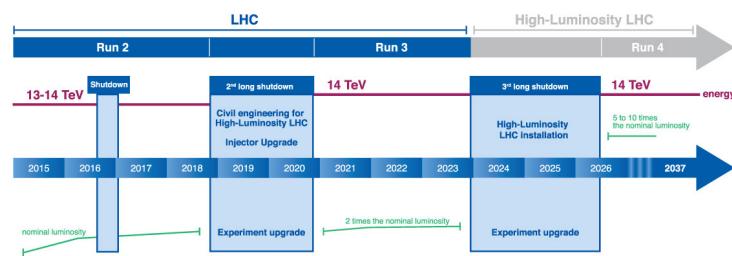

Fig. 5.1: Timeline for LHC [15]

368

The increased luminosity results in more interactions per bunch crossing or pileup. In order to limit the amount of pileup the experiments must

disentangle to more manageable levels, the nominal scenario would be operating at a stable luminosity of $5.0 \times 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$. This would limit the pileup to an average of 140. The ultimate scenario for operations would be running at $7.5 \times 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$ which brings the average pileup up to 200. The CMS detector in its current state is not capable of dealing with $\approx 140\text{-}200$ pileup. At this level of pileup the spacial overlaps of tracks and energy depositions would lead to a degradation in the ability to identify and reconstruct hard interactions. In order to preserve the data quality of the current CMS detector this increased pileup must be reduced to an equivalent level approximately equal to current LHC operations which is ~ 40 . The collision vertices within a bunch crossing have an RMS spread of 180-200 ps in time. If the beam spot were to be sliced into consecutive snap shots of 30-40 ps then the pileup levels per snapshot would be approximately 40. The space-time reconstruction of a 200 pileup event is shown in Figure 5.2. The addition of timing information to the z position spreads apart the vertices that would otherwise have been merged together and indiscernible. In order to achieve this a detector dedicated to the precise timing of minimum ionizing particles (MIPs), the MTD, will be added to the CMS detector.

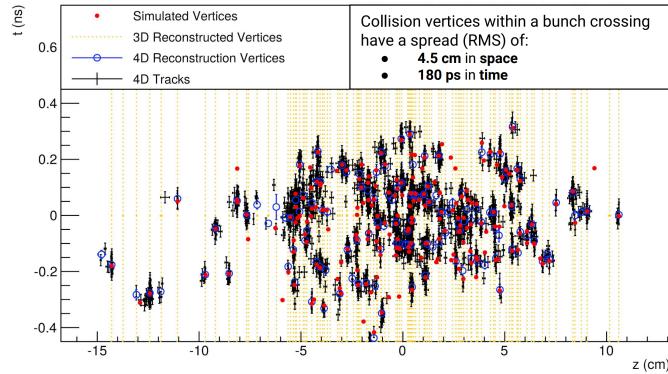

Fig. 5.2: Vertices from a simulated 200 pileup event. Need to replace this with the figure from the TDR.

388

5.2 Barrel Timing Layer

389 The Barrel Timing Layer (BTL) makes up the barrel region of the MTD.
 390 It will provide pseudorapidity coverage up to $|\eta| = 1.48$ with a geometric
 391 acceptance of $\sim 90\%$. The BTL will be capable of detecting MIPs with a
 392 time resolution of 30 ps at the start of Phase-2 operations and a luminosity-

³⁹³ weighted time resolution of ~ 45 ps when radiation damage effects are taken
³⁹⁴ into account.

6. CMS TRIGGER SYSTEM

396 When operating at nominal luminosity the LHC produces over 1 billion
 397 proton-proton collisions per second. Finite computing speed and storage
 398 capacity limit the rate at which CMS can record events to be about 1 kHz
 399 [8]. Decreasing the rate from 1 GHz to 1 kHz is accomplished by using a
 400 two-level trigger system to quickly decide which events will be discarded
 401 and which will be recorded. The first stage is a hardware-based Level 1 (L1)
 402 trigger and the second stage is software-based High Level Trigger (HLT).

6.1 *L1 trigger*

404 The L1 trigger decreases the rate by about six orders of magnitude from 1
 405 GHz to 100 kHz by performing rough calculations on information from the
 406 ECAL, HCAL, and muon subsystems using field-programmable gate arrays
 407 (FPGAs). The L1 trigger can be divided further into the calorimeter and
 408 muon triggers. The schematic of the L1 trigger system in Figure 6.1 shows
 409 both the calorimeter and muon triggers. The calorimeter trigger trigger
 410 uses information from the ECAL and HCAL subdetectors to construct pho-
 411 ton, electron, and jet candidates in addition to quantities such as missing
 412 transverse momentum and total hadronic activity. The muon trigger uses
 413 information from all three muon subsystems to construct muon candidates.
 414 The outputs from the calorimeter and muon triggers goes into the Global
 415 Trigger (GT) which decides which events should be recorded and which are
 416 to be discarded [20].

6.1.1 *Calorimeter trigger*

418 Trigger Primitives (TP) are the raw inputs from the ECAL and HCAL
 419 for the calorimeter trigger. The TP, which contain information regarding
 420 the energy deposits in the calorimeters, are passed to the first layer of the
 421 calorimeter trigger. This first layer consists of several FPGA cards that
 422 receive data from several bunch crossings, but are each mapped to a section
 423 of the detector. This data is then passed on to the second layer in such a way

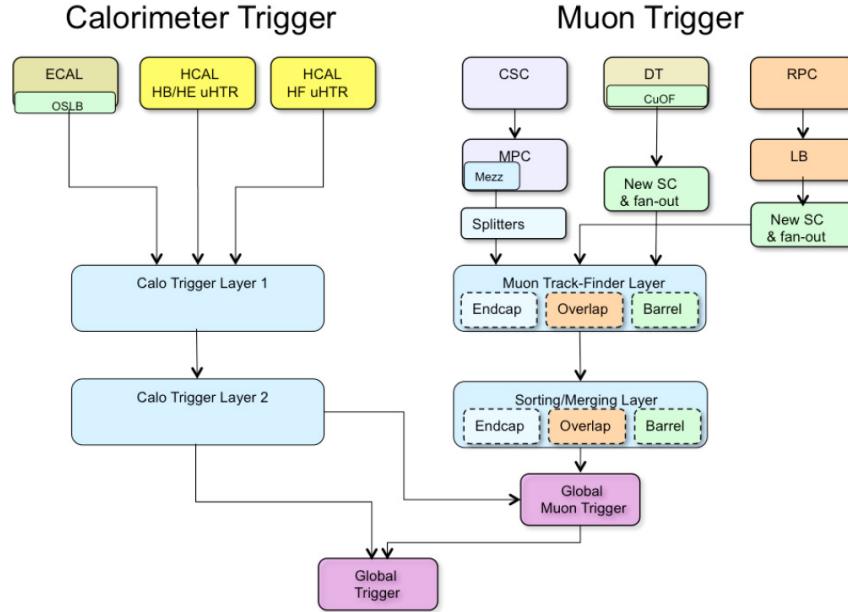

Fig. 6.1: L1 trigger system. Reprint from [3]

424 that each FPGA in this layer will receive data for the entire calorimeter for
 425 each bunch crossing. Candidate objects are then constructed and organized
 426 into a sorted list according to transverse momentum and passed on to the
 427 GT and the global muon trigger.

428 6.1.2 Muon trigger

429 TP for the muon trigger come from the three muon detectors, the CSCs,
 430 DTs, and RPCs. These are then passed on to the first layer of the muon
 431 trigger (Muon Track-Finding Layer) where the TP are combined to recon-
 432 struct muon tracks for sections of ϕ for different regions of $|\eta|$. The barrel
 433 track-finder for $|\eta| < 0.83$, the endcap track-finder for $|\eta| > 1.24$, and the
 434 overlap track-finder for $0.83 < |\eta| < 1.24$. This data is passed on to the
 435 second layer where the sections of ϕ are merged and subsequently passed
 436 on to the global muon trigger where it is combined with the output from
 437 Calo Trigger Layer 2 to compute isolation. The global muon trigger then
 438 combines the η regions and passes a list of the top eight muon candidates
 439 to the GT.

 440 *6.1.3 Global Trigger*

441 Final processing of the reconstructed objects and quantities constructed by
 442 the calorimeter and muon triggers is carried out by the GT. L1 algorithms
 443 or "seeds" are implemented by the GT using these objects. A full set of L1
 444 seed is called a L1 menu and can be adjusted to meet the requirements of
 445 the CMS physics program. Each L1 seed can be given a "prescale", which is
 446 an integer value N that can be used to reduce the rate of a particular trigger
 447 path. This is done by only applying the trigger to one out of N events and
 448 can be used to take advantage of the current LHC running conditions.

 449 *6.2 High Level Trigger*

450 Events that are accepted by the L1 trigger are passed on to the HLT which
 451 is based in software and is therefore capable of analyzing events with a higher
 452 degree of sophistication. The HLT has access to information from the full
 453 detector and implements "paths" to select events of interest from those pass-
 454 ing the L1 trigger. Each HLT path is a set of criteria that is used to either
 455 accept or reject an event. The full set of HLT paths is the HLT menu. Each
 456 HLT path is "seeded" by one or more L1 seeds in order to decrease comput-
 457 ing time. That means that a given HLT path will only be processed if the
 458 L1 bits associated with its seed or seeds fire. Each HLT path is assigned to
 459 a primary dataset depending on its general physics signature. In the case
 460 of this analysis, the primary dataset used for signal events was DoubleEG
 461 for years 2016 and 2017. This was merged into the EGamma dataset for
 462 2018. The SingleMuon dataset was used for trigger efficiency studies. A list
 463 of the primary HLT used for each year along with its associated primary
 464 dataset is listed in Table 6.1. The HLT path for 2016 is different because
 465 HLT_DoublePhoton70 was not a part of the HLT menu until 2017.

Tab. 6.1: Primary HLT

Year	HLT path	Primary dataset
2016	HLT_DoublePhoton60	DoubleEG
2017	HLT_DoublePhoton70	DoubleEG
2018	HLT_DoublePhoton70	EGamma

 466 *6.3 Trigger efficiency*

467 7. CMS PARTICLE AND EVENT RECONSTRUCTION

468 After an event is chosen to be stored by the trigger system, the output from
469 all of the sub-detectors is saved and recorded to disk as "RAW" data. These
470 data contain information about the response of each sub-detector, such as
471 tracker hits and energy deposition in the calorimeters. As was mentioned
472 in Chapter 4, shown in Table 4.1 and Figure 4.2, the CMS was designed
473 such that each type of particle resulting from the pp collisions at the IP
474 would leave a distinct signature in the sub-detectors. This allows for the
475 information to be reconstructed into lists of physics object candidates such
476 as photons, electrons, muons, etc and quantities such as missing transverse
477 momentum. The particle flow (PF) algorithm performs this reconstruction
478 by first building tracks and calorimeter clusters. These two elements are the
479 inputs to the reconstruction of the aforementioned physics object candidates
480 using a "link" algorithm.

481 7.1 *Tracks*

482 A combinatorial track finder algorithm based on the Kalman filtering tech-
483 nique uses the hits in the silicon tracker to reconstruct tracks of charged
484 particles [17]. Each iteration of the algorithm is comprised of three steps:

- 485 • Seed generation: Find a seed consisting of two to three hits that is
486 compatible with a track from a charged particle.
- 487 • Track finding: Use pattern recognition to identify any hits that are
488 compatible with the trajectory implied by the seed generated in the
489 first step.
- 490 • Track fitting: Determine the properties of the track, such as origin,
491 trajectory, and transverse momentum by performing a global χ^2 fit.

492 The first iteration uses stringent requirements on the seeds and the χ^2
493 of the track fit to pick out isolated jets which have very high purity. The
494 hits associated with these high purity tracks are then removed to reduce the

495 combinatorial complexity for subsequent iterations. This allows successive
496 iterations to identify less obvious tracks by progressively loosening criteria
497 while the removal of previously associated hits mitigates the likelihood of
498 fake tracks being built.

499 **7.2 Calorimeter clusters**

500 Calorimeter clusters are constructed using energy deposition information
501 from the calorimeters. Clusters are formed by first identifying the seed cell
502 (ECAL crystal or HCAL scintillating tile) that corresponds to the local
503 maxima of an energy deposit that is above a given threshold. Neighboring
504 cells are then aggregated to grow topological clusters if their signals are
505 above twice the standard deviation of the level of electronic noise.

506 **7.3 Object identification**

507 At this point the tracks and calorimeter clusters are linked to form a PF
508 block. This linkage is done with an algorithm that quantifies the likelihood
509 that a given track and cluster were results of the same particle. As PF locks
510 are identified as object candidates they are removed from the collection prior
511 to each subsequent iteration until all tracks and clusters have been assigned
512 to a PF object candidate. The following sections will outline how each of
513 these PF objects is identified.

514 **7.3.1 Muons**

515 Muons are the easiest particle to identify, so they are the first objects recon-
516 structed in the CMS. PF Muons are classified in three categories depending
517 on how their tracks are reconstructed:

- 518 • Tracker muons: Tracks reconstructed from the inner tracker having
519 $p_T > 0.5$ GeV and $|\vec{p}| > 2.5$ GeV that, when propagated to the muon
520 system, match at least one hit in the muon chambers.
- 521 • Stand-alone muons: Tracks reconstructed only using hits in the muon
522 system.
- 523 • Global muons: Stand-alone muons that coincide with a track from the
524 inner tracker.

525 After a muon is reconstructed it is given an identification or ID based on
526 observables such as the χ^2 of the track fit, how many hits were recorded

527 per track, or how well the tracker and stand-alone tracks matched. These
528 IDs represent different working points (loose, medium, and tight) which
529 correspond to increasing purity but decreasing efficiency as you move from
530 loose toward tight.

531 **7.3.2 Electrons**

532 **7.3.3 Photons**

533 **7.3.4 Jets**

534 **7.4 Missing transverse momentum**
